

CHEMICAL-BIOLOGICAL PROCESS FOR THE REMOVAL OF H₂S FROM A GAS

5

CHEMICAL-BIOLOGICAL PROCESS FOR THE DESULFURIZATION OF
GASEOUS STREAMS CONTAINING H₂S.

The present invention relates to a chemical-biological
10 process for the desulfurization of gaseous streams contain-
ing H₂S.

More specifically, the present invention relates to a
chemical/biological process for the desulfurization of
gaseous streams containing H₂S capable of operating stably
15 and effectively in continuous regime.

Hydrogen sulfide is a polluting gas which is found in
nature, in natural gas and in biogas, but it is also pro-
duced in gaseous streams by the chemical industry, in oil
refining and the gasification of carbon. It is also often
20 present in the effluents of industrial plants.

The article "Rounding Up Sulfur" published in Chemical
Engineering of February 1995 describes numerous chemical
methods for the separation of this pollutant.

The most widely-used technologies for desulfurizing
25 gaseous streams are based on the Claus reaction between hy-

drogen sulfide and sulfur dioxide to give elemental sulfur and water. This approach is widely used for a vast range of applications which require a high adaptation capacity to specific operating necessities, as recently described in 5 the article: Recovery of Sulfur from Sour Gas: A Review of the technology; published by Environmental Progress in 2002 (vol. 21 Nr. 3).

Claus technologies require large investments, they cannot be applied directly to the treatment of natural gas 10 and they are not normally used for gaseous streams containing quantities of sulfur lower than 15 t/day. In these cases redox technologies, which operate in liquid phase, are considered more advantageous.

Many of these technologies use the ferric ion as oxidizing agent of the sulfide ion for the generation of elemental sulfur. Once the reaction has been completed, the solid sulfur is separated by filtration or centrifugation and the ferric ion is re-obtained by catalytic oxidation with air, the whole process is described for example in 15 20 "Gas industry assesses new ways to remove small amounts of H₂S, Oil & Gas Journal of May 23, 1994.

A very efficient catalytic oxidation system with air of the ferrous ion to the ferric ion exploits the capacity of *Thiobacilli*, in particular *Thiobacillus ferrooxidans*, 25 which are capable of accelerating, in an acid environment,

the natural oxidation rate by about 500,000 times.

On the basis of these elements, right from the beginning of the twentieth century, attempts have been made to develop separation processes of H₂S based on the following reactions:

Considerable advantages can be potentially obtained by exploiting the above reactions:

- the chemical reaction (1) is almost instantaneous and can be carried out with relatively high concentrations of the iron ion, without the necessity of using organic complexing agents, if operating with acid pH values which limit the precipitation phenomena of the reagent in the form of hydroxides;
- the biological reaction (2) takes place spontaneously at a temperature close to room value, it does not envisage the consumption of costly products as *T. ferroxidans* is a micro-organism which only requires carbon dioxide (present in the air) and simple mineral salts, for its own multiplication. There are no problems of sterility as *Thiobacilli* are the only micro-organisms which are capable of multiplying at strongly acid pH values, using only the energy obtained from the oxidation of the ferrous ion to the ferric ion;

- the separation processes of H₂S based on the joint exploitation of the two reactions, are extremely versatile, as they can be used in almost all applicative contexts and are very flexible to changes, also sudden, in the composition of the gas to be treated.

In spite of these advantages, the development of technologies based on the exploitation of reactions (1) and (2) is hindered by the necessity of overcoming the following main problems:

- 10 - the production of sulfur, in crystalline form, which can be easily separated from reaction (1), is critical for maintaining the continuity of the unitary operations, for minimizing the loss of the iron ion and obtaining a product with a sufficient purity for market demands;
- 15 - the alignment of the two reactions is based on a very delicate equilibrium on which the stability of the continuative running of the two main unitary operations forming the process, depends. One of the critical parameters of this equilibrium consists, for example, of the pH which can 20 vary only within a very narrow range, normally between 1.4 and 2.0. Below the minimum value, the activity of *T. ferroxidans* is inhibited; over the maximum value precipitation phenomena of the ferric ion are triggered;
- another critical parameter consists of maintaining the 25 correct concentrations of ammonium, phosphate, potassium

and magnesium ions, necessary together with CO₂, for the multiplication of *T. ferroxidans*. The formation of insoluble precipitates of jarosites is known - under the operating conditions normally used for exploiting the reaction

- 5 (2) - for example potassium [KFe₃(SO₄)₂(OH)₆], which subtract Fe⁺³, NH₄⁺, K⁺ and OH⁻ from the system, at the same time contributing to an acidification of the liquid stream (Anders B. Jensen & Colin Webb, Ferrous Sulphate Oxidation Using *T. ferroxidans* (1995) Progress Biochemistry 30, 225-10 236; C. Pogliani & E. Donati Immobilization of *T. ferroxidans*: importance of jarosites precipitation (2000) Progress Biochemistry 35, 997-1004);
- the modest efficiency of the common oxidation systems of the ferrous ion to the ferric ion biocatalyzed by *Thiobacilli*. This creates economic and technological problems, for the practical use of reaction (2), of having to adopt reactors having considerable dimensions.

According to literature data, many technological approaches have been proposed, aimed at exploiting reactions 20 (1) and (2) and overcoming or limiting the effect of the practical problems mentioned above.

The patent EP 220776, for example, describes a chemical-biological desulfurization process which exploits reactions (1) and (2) in which the bioreactor, where the ferric 25 sulfate is regenerated, operates with micro-organisms in a

suspended medium which are recovered from the solution containing oxidized iron with the use of ultra-filtration membranes, thus maintaining a high cellular concentration and at the same time obtaining sulfur with a higher degree of
5 purity.

Patent EP 280750 describes a chemical-biological desulfuration process which exploits reactions (1) and (2), in which the bioreactor contains a solid carrier on which iron-oxidizing bacteria have been deposited, which operate
10 in a submersed medium. In this way it is possible to raise the efficiency of the bioreactor, at the same time limiting the bacterial contamination of the sulfur produced. EP 280750 also describes examples for effecting the process in continuous, which however are limited to a period of three
15 days and do not provide details on the operating procedure.

Patent EP 811416 describes a chemical-biological desulfurization process based on the exploitation of reactions (1) and (2), in which the oxidation of the ferrous sulfate takes place in a bioreactor containing a solid carrier covered by a biofilm of iron-oxidizing bacteria of the *Thiobacillus* type, which operate in an immersed medium (trickling-bed). The process enables a better productivity to be obtained (referring to g of Fe²⁺ oxidized per h and per liter of the reactor), with respect to that obtained in
20 the biotechnological processes described in the known art.
25

EP 811416 also describes the possibility of carrying out reaction (1) at temperatures higher than room temperature thus obtaining a more easily separable crystalline sulfur.

5 None of the documents cited, however, faces problems relating to compatibilization/alignment between the chemical step and the biological step with the final objective of obtaining a process for desulfurizing a gaseous fluid containing H₂S which can be stably run in continuous regime
10 and which, at the same time, is reliable, flexible and has a high separation capacity of the H₂S.

Furthermore, no document provides details on the continuous functioning of the integrated system consisting of the chemical step and the biological step.

15 A chemical-biological process has now been found for the desulfurization of gaseous streams containing H₂S which overcomes the problems of compatibilization/alignment between the chemical step and the biological step and which can be run stably, in continuous regime, with reliability,
20 flexibility and a high separation capacity of the H₂S.

In accordance with this, an object of the present invention relates to a continuous process for the desulfurization of gaseous streams containing H₂S, comprising, according to the scheme provided in Figure 1:

25 (a)- feeding to the bottom of an absorption column (RC) op-

erating at room temperature and at a pressure normally ranging from 1 to 1.2 Atm, a gaseous stream (1) containing H₂S at concentrations ranging from 10 ppmv to 99% vol/vol;

5 - feeding to the same column a liquid stream (2), removed from the bottom of a biological reactor (RB), containing a solution of ferric/ferrous sulfate with total concentration ranges of iron of 0.1-0.5 M and molar ratios within the range (100:0 up to 60:40), with pH values within the range of 1.40-1.90;

10 - streams 1 and 2 being fed in such quantities that the ratio in moles between the H₂S and ferric iron ranges from 1:20 to 1:4;

(b) - extracting the gaseous stream (3), purified of H₂S, from the head of the absorption column RC, together with a
15 stream (4) consisting of a solution of ferrous/ferric sulfate in which the concentration of the Fe²⁺ ion ranges from 0.025 to 0.15 M, in which elemental sulfur is suspended in the form of crystalline particles with an average particle size higher than 70 µm at concentrations within the range
20 of 0.1-5 g/l;

(c) - feeding said stream (4) to a filtration system;

(d) - extracting from the filtration system a limpid stream

(5) consisting of a ferric:ferrous sulfate solution in a molar ratio within the range of 80:20-40:60, at total iron
25 concentrations ranging from 0.1-0.5 M and pH ranges of

1.90-1.50;

- extracting a solid stream (6) with a sulfur content of 50-70% from the filtration system;

(e) - resuspending in a stirred reactor the solid stream

5 (6) of raw sulfur in a quantity of water equal to the overall amount lost by evaporation from the process and feeding the suspension thus obtained to a filtration system;

(f) - extracting from the filtration system a limpid stream

(7) consisting of a solution of ferric:ferrous sulfate and

10 a solid (8) consisting of sulfur at 98-99.5% of purity;

(g) - feeding stream (9) obtained by mixing streams (5) and

(7) containing ferrous sulfate, ammonium hydroxide and ammonium phosphate, to the top of the biological reactor (RB), consisting of a trickle-bed containing an acid-resistant carrier colonized by *Thiobacillus ferrooxidans*, in the quantities necessary for maintaining the concentrations of the above salts within the ranges of 0.1-0.5 M, 1-10 mM, 0.2-2 mM, respectively;

(h) - feeding to the bottom of the biological reactor a

20 gaseous stream (10) consisting of air or air enriched with O₂/CO₂.

The process, object of the present invention, allows the chemical step to be stably and effectively aligned with the biological step, for the regeneration of the ferrous 25 ion to the ferric ion and, without the use of additives or

flocculating agents, the sulfur produced, to be easily and efficiently separated. In practice, crystalline particles are obtained with an average particle size higher than 70 µm, with considerable simplifications of the sulfur separation section.

In particular, the biological reactor operates with adhered biomass under trickle-bed conditions, efficiently oxidizing the ferrous ion.

Furthermore, the formulation of the culture medium allows the pH to be regulated between the two steps, eliminating the risk of occlusions of insoluble precipitates on the biocatalytic carrier.

The process, object of the present invention, forms a "zero discharge" productive system, as it does not generate any type of effluent. In addition, the characteristic of the autotrophous strain allows an amount of CO₂ equal to 15 Kg/t of sulfur produced to be separated.

More specifically, the process, object of the present invention, schematized in Figure 1, operates in continuous and is based on four main unitary operations: chemical reaction, biological reaction, removal of sulfur and restoring of the process liquid (make-up).

The chemical absorption reactor (RC) consists of a bubble column which operates at room temperature, with pressure values normally ranging from 1 to 1.2 Atm, but

which, with simple modifications, can also operate under pressure. At the head of the RC there is a level controller which regulates the flow-rate of the feeding pump of the oxidized substrate coming from RB in relation to the flow-
5 rate of the extraction pump with which the sulfur suspension is transferred to the filtration section.

The flow of the gaseous stream (1) is regulated by a MF (Mass flow controller) and normally consists of H₂S, carbon dioxide, nitrogen, methane, other hydrocarbons and,
10 possibly, traces of COS, CS₂, mercaptans. The feeding of the gas to RC is effected through one or more gas-spargers made of Teflon with pores of about 10 µm.

The ratio between the H₂S and other gaseous components can range from 10 ppm to 99% ppm by volume. The flow and
15 H₂S content in said stream can be either fresh or recycled reagents, coming from the head of the chemical reactor RC.

The liquid phase (2), consisting of ferric:ferrous sulfate produced by the biological reactor RB, is sent to RC in equicurrent or in countercurrent, by means of a volumetric pump. The solution more specifically consists of ferric:ferrous sulfate with total iron concentration ranges
20 of 0.1-0.5 M and molar ratios within the range (100:0 to 60:40), with pH values within the range of 1.90-1.40.

The composition of the softened gas leaving the RC
25 section (3) is kept under control by means of gas-

chromatographic analysis to mainly determine its content of residual H₂S, which normally varies from values close to zero to 10 ppmv.

The suspension of elemental sulfur which is formed in
5 RC is maintained at a value of total suspended solids rang-
ing from 0.1 to 5 g/l. The slurry (4) consisting of a solu-
tion of ferrous/ferric sulfate in which the concentration
of the Fe²⁺ ion ranges from 0.025 to 0.15 M, preferably
0.10 M, in which elemental sulfur is suspended, is removed
10 and sent, by means of a volumetric pump, to the filtration
system, for example of the vacuum-filter type.

The partially reduced limpid substrate (5), leaving
the filtration system, consists of ferric:ferrous sulfate
with total concentration ranges of the iron ion of 0.1-0.5
15 M and molar ratios Fe³⁺/Fe²⁺ within the range of 80:20 to
40:60, with pH values within the range of 1.90-1.50. The
limpid substrate is sent, through the make-up reactor, to
RB where it is regenerated.

The sulfur separation system generates a product,
20 stream (6), with a total solid content of 50-70% and a de-
gree of purity of 90-92%. A simple washing with water is
sufficient to recover most of the ions present, obtaining a
product (8) at 98-99.5% of purity.

The water and substrate recovered with the washing (7)
25 is added to the make-up tank to compensate the loss of wa-

ter by evaporation from the vacuum-filter and RB.

The biological reactor RB consists of a steel column of which 80% is filled with a solid acid-resistant carrier in a trickle-bed configuration. This configuration allows
5 the contact to be maximized between the micro-organisms adhering to the inert carrier, the aqueous stream (containing ferrous sulfate) and the air - supplier of carbon dioxide (the sole carbon source for the growth of the micro-organism) and oxygen for the oxidation of the ferrous ion
10 to ferric ion. The procedure used for the colonization of the catalytic carrier has already been described in a previous patent EP 811416 filed by the same applicant. The carrier is colonized by *Thiobacillus ferroxidans* which expresses its activity at strongly acid pH values (1.4-2.2);
15 this extreme survival niche reduces the risk of competitors of the oxidation reaction, eliminating costly sterilization processes of the substrate. This makes it possible to operate on solutions with high concentrations of iron, maintaining a high separation efficiency of the H₂S (reaction
20 1) and subsequent bio-oxidation (reaction 2).

The catalytic carrier is fed to the bottom by air or air enriched with O₂/CO₂ with a flow within the range of 0.8-16 vol/volume of reactor/h. The liquid stream is fed from above with flow-rates corresponding to hydraulic re-
25 tention times ranging from 2 to 7 minutes. After wetting

the carrier, the liquid stream is poured into an underlying container to be recycled. The reagents contained in the stream (2) can be either fresh or recycled reagents, coming from the RC section.

5 Furthermore, the stream 2 contains nutrients: nitrogen and phosphorous, which, together with the CO₂, form macro-nutrients, whereas the ferrous ion is the primary energy source. In the process, object of the present invention, the nitrogen source is ammonium hydroxide in a concentration varying from 1 to 10 mM, the phosphorous source is ammonium phosphate at a concentration varying from 0.2 to 2 mM. The formulation adopted allows the nutritional requirements of the micro-organism to be satisfied, minimizing the risk of the formation of insoluble jarosite precipitates,

10 such as: K₂Fe₃(SO₄)₂(OH)₆ on the carrier.

15

The total iron ion concentration ranges normally used vary from 0.1 to 0.5 M, preferably 0.3 M and the molar ratios (ferric:ferrous) are within the range of 100:0 to 60:40, under these conditions the operative pH varies

20 within the range of 1.90 to 1.50 units.

The feeding of the ferrous ion is ensured by stream 9, coming from the make-up section, after recovering the sulfur. The oxidized substrate (2) which serves to feed the chemical reactor RC, to complete the cycle, is removed from

25 the bottom of the accumulation container.

By operating according to the process, object of the present invention, the operating costs are lowered, with a reduction in energy consumption, chemicals and labour necessary for the running of the process. Thanks to the considerable efficiency of the biological reactor and high concentration of the ferric ion used, the volumes of the two main RC and RB reactors are also minimized, thus reducing the process investment costs.

**EXAMPLE 1 - Desulfurization of gas from desorption on
10 amines.**

The experiment was carried out in continuous and programmed to reveal: the start-up phase, the operating flexibility of the bio-reactor with fluctuations in the concentration of H₂S and finally, the stability of the system.

15 The start-up phase lasted about 15 days. In particular, with reference to figure 1, the gaseous stream 1 derives from a gaseous stream obtained from a plant using amines for the softening of natural gas with an H₂S:CO₂ composition equal to 60:40 vol/vol. The flow-rate of this
20 stream was progressively increased by 270%, compatibly with the increase in the biological activity, the concentration of H₂S being kept constant at 60% vol/vol. In the reactive absorption phase, the gaseous stream 1 is mixed with the liquid stream 2, containing ferric sulfate, in such quantities that the ratio in moles between H₂S and the ferric ion
25

ranges from 1:20 to 1:4, said ratio in moles normally being 1:10. These ratios usually lead to a variation of 5 to 25% in the percentage of ferrous ion in the stream 5, equal to an oscillation of 0.05-0.25 units of pH, normally restored 5 by the biological activity. At the end of the start-up period there is a catalytic carrier capable of expressing productivity values of about 3.5 U (g of Fe⁺³ produced h⁻¹ per liter of total volume of carrier).

A softened gaseous stream 3, with a residual content 10 of H₂S lower than 4 ppmv, is produced in the chemical reactor RC, normally using a height of the liquid seal not exceeding 200 cm.

After the start-up period with a productivity of 3.5 U, the stability of the system was determined for periods 15 of not less than 4 weeks of continuous running. For this purpose, the following parameters were maintained constant: the charge and concentration of H₂S at 60%; the molar ratio between the H₂S in the gaseous stream 1, and the ferric sulfate, in the solution 2, equal to 6; the air flow to the 20 biological reactor; the temperature of the aqueous medium between 24 and 35°C. Under these conditions, practically constant percentages of ferrous ion in streams 2 and 5 were recorded. More specifically, the percentage of ferrous ion and the pH value of stream 2 varied within the range of 8- 25 12% and 1.75-1.82 units, respectively; the percentage of

ferrous ion in stream 5, on the other hand, was kept within the range of 18-22% with pH values of 1.66-1.74. These limited oscillations can be attributed to the day/night thermal swing which influenced the operating temperature of the 5 plant. Under these conditions, the residual concentration of H₂S in stream 3 at the outlet of the absorber reaches and maintains the value of 4 ppmv.

The sulfur separation system ensured a raw product having a purity of 90-92% with a percentage of dry substance varying from 50 to 60%. A simple washing of the raw 10 product, with deionized water, is sufficient to recover over 85% of ferrous sulfate soaked therein, producing sulfur having a purity of 98%.

The flexibility of RB with fluctuations of the ferrous 15 ion charge was determined over a continuous operating period of not less than 4 weeks, cyclically varying the H₂S charge and maintaining it constant for three days at two levels, one the double of the other. In particular, by varying the concentration of H₂S in the in-flowing gas between 20 15 and 30%, the biological reactor can alternately operate in situations of hypo-feeding and hyper-feeding at 13.4 and 35.7 moles respectively Fe/h, m³ of RB. At the lowest and highest level of the charge, the biological reactor RB operated on an average with percentages of oxidized substrate of 90-95% and 80-85%, with pH values of 25

1.85 and 1.75, respectively. Under the same conditions, the chemical reactor RC allowed a percentage of ferric ion within the range of 70-75% and 60-65% respectively, to be reached, with pH values of 1.70 and 1.60 units. Under these 5 conditions, the productivity of the biological reactor was established on an average at 1.5 and 3.0 U, respectively, with a low and high H₂S charge.

The best process performances were tested by subjecting the system to increasing charges of H₂S, with the condition that the concentration of H₂S in the softened gas of stream 3 remain equal to or lower than 4 ppmV. Under these 10 conditions, a productivity on the biological reactor corresponding to 4.5 g of ferric ion produced h⁻¹ per liter of total carrier was recorded, which is much higher than other 15 known processes specified in literature. With the maximum H₂S charge, at a concentration in the in-coming gas of 60%, efficiency values of the chemical reactor of over 11.0 g of sulfur separated per liter of RC h⁻¹ were obtained, with separation percentages close to 100%, even with a liquid 20 seal height reduced to 180 cm.

EXAMPLE 2 - Desulfurization of Biogas

The stream (1) used consisted of: methane 81%, CO₂ 8%, H₂S 8% and nitrogen 3%, the flow of gas treated was progressively increased between 23 vol/vol of RC/h⁻¹ and 91 25 vol/vol of RC/h⁻¹, operating at a pressure of 1.1 Atm and

at room temperature. The height of the seal established in RC was 180 cm, with which a softened gas completely free of H₂S was obtained. Under these operating conditions, the productivity of the biological reactor oscillates from 1 to 5 4 U (grams of ferric ion produced h⁻¹ per liter of total catalytic carrier). The percentage of ferrous ion recorded on the stream (2) varied from 5 to 20%, the pH values registered on stream (2) oscillated from 1.80 to 1.72 units.

EXAMPLE 3 - Direct desulfurization of natural gas

10 The natural gas is characterized by high flows with a low content of hydrogen sulfide, in this case stream (1) consisted of: methane 91%, CO₂ 6%, H₂S 0.6% and nitrogen about 2%. The flow treated was constantly equal to 28 vol/vol(RC)/h, the operating pressure 1.2 Atm, operating at 15 room temperature and with a liquid seal height of 130 cm. Under these hypo-feeding conditions, the biological reactor generated a stream (2) with a percentage of ferric ion within the range of 92-96% and pH values of around 1.85 units. The stream (5) expressed a percentage of ferric ion 20 of 80 to 85% and pH values of 1.75-1.80. The softened gas of the outgoing stream (3) was free of H₂S.
